

The Impact of European Integration on Wage Differentials in the Bavarian-Czech Border Region

Michael Moritz[#]

Institute for Employment Research, Nuremberg

Abstract: In the process of European integration labour markets are assumed to be affected disproportionately in regions bordering on new EU member countries. With respect to wage differentials, compared to interior regions, low-skilled workers there are according to the Feenstra-Hanson model predicted to suffer notably from increasing trade and the relocation of production activities to low-wage countries, while high-skilled workers should benefit from the increasing market potential. Using data from the IAB employment subsample (IABS) and the employment register (BeH) I shed light on the development of the wages for workers in eastern Bavaria compared to other western German districts. Conducting regressions separately for every year and a fixed effects approach I come to surprising results: while in the early years after the fall of the Iron Curtain a catching-up process set in for the bulk of employees in eastern Bavaria, the trend reverses after 1995 and the wage gap deepens again.

Zusammenfassung: Die Arbeitsmärkte in Grenzregionen zu den mittelosteuropäischen EU-Mitgliedern sind durch die wirtschaftliche Integration Europas besonders betroffen. Durch die geographische Nähe sollten sich dort die relativen Änderungen in der Arbeitsnachfrage überdurchschnittlich auswirken. Dem Feenstra-Hanson-Modell zufolge verlieren geringqualifizierte Arbeitnehmer im Grenzland überproportional, während Hochqualifizierte die Gewinner der Handelsliberalisierung sind. Auf Basis der Daten der IAB-Beschäftigtenstichprobe und der Beschäftigten-Historik schätze ich die Lohndifferenziale zwischen Arbeitnehmern in der Grenzregion Ostbayern und dem restlichen westdeutschen Bundesgebiet. Die Ergebnisse überraschen: während es Anfang der 1990er Jahre für einen Großteil der Arbeitnehmer zu einem Aufholprozess in Ostbayern kommt, dreht sich der Trend ab 1995 und der Lohnabstand wächst wieder.

1 Introduction

In the course of globalisation and the EU enlargement process the labour markets in western European countries have to face intense cost pressure. Especially the population at the immediate frontier between old and new EU member states is affected by fundamental changes in the economic framework. The unexpected fall of the Iron Curtain in 1989 meets the criteria of a natural experiment. Though border regions should profit due to increasing trade possibilities in the long run, they have to cope with adjustment problems in particular on the labour market. Although free movement of labour and freedom of services is still restricted in a transition period not exceeding 2011, the districts in eastern Bavaria close to the Czech Republic have to bear growing international outsourcing activities and import competition from the neighbouring country. Against this background the question arises, what impact the increasing economic integration had on the development of wages in the districts close to the border. While traditional trade models deal with the distribution of horizontal production across countries (models by Ricardo, Heckscher-Ohlin, Stolper-Samuelson theorem), new trade theory tries to explain the phenomenon of intra-industrial trade and the fragmentation of production. One of the most important models from this group of the literature is the Feenstra-Hanson model, which was developed in the course of the increasing outsourcing activities from the United States to Mexico. In the model developed by Feenstra/Hanson (1996) a single manufactured good is produced in two countries (home and foreign, $i=1,2$) from a continuum of intermediate inputs using unskilled labour (L_i), skilled labour (H_i) and capital (K_i). The factor prices are given by the wage for unskilled labour, w_i , the wage for skilled labour, q_i and the rental on capital, r_i . $z \in [0,1]$ denotes the many different activities necessary for the production of a final good whose production needs no additional input of labour or capital. A higher value of z is equivalent to an input that uses skilled labour more intensively. It is assumed that unskilled labour is relatively scarce and skilled labour relatively abundant in the home country. Therefore unskilled labour is relatively more expensive at home than abroad. z^* denotes the equilibrium value, i.e. the critical value regarding the fragmentation of production between the home and the foreign country. Since according to the above assumption the wage of skilled employees is relatively lower in the home country, all activities $z' > z^*$ can be produced advantageously at home. On the other hand all activities $z' < z^*$ can be produced at a cheaper rate in the foreign country. As a consequence the foreign country specialises in activities $[0, z^*)$, whilst the home country specialises in activities $(z^*, 1]$. The assumption that the rental on capital r is lower in the home country ($r_1 < r_2$), reflects the relative abundance of

capital at home. Allowing for capital mobility between the two countries, capital will move abroad, so that K decreases at home and increases abroad. This results in rising capital costs in the home country, while in the foreign country the capital rent will shrink. Consequently, due to the modified cost structure, the equilibrium value of z increases, i.e. the foreign country specialises in an expanded range of activities, while the home country specialises in a contracted range of activities. This has the following implications regarding the demand for labour: the production activities which are outsourced from the home to the foreign country use skilled labour less intensively than the activities which still are produced at home. Hence, the relative demand for unskilled labour drops in the home country, the relative demand for skilled labour rises. In the foreign country the allured activities use relatively more skilled labour than the hitherto performed activities, leading to a growing demand for skilled labour there, too. Unlike in the Heckscher-Ohlin-Samuelson framework the relative wages of skilled labour rise in both countries.

The essential conclusion of this theoretical model is that even without explicit consideration of distance, hypotheses for EU border regions in Western Europe can be derived. In general, labour market effects of economic integration are especially large in the borderland due to lower transport and transaction costs. Low-skilled workers are supposed to lose out above-average there, while high-skilled workers should especially profit in districts close to the new markets. This standpoint is reflected in the European Commission's report on EU-15 border regions (European Commission 2001: 10): "In general, human capital-intensive and technologically advanced sectors in the border regions are likely to benefit from enlargement, while labour-intensive sectors are likely to face increased competition from cheap labour."

As in the theoretical field for the matter of empirics the studies by Feenstra and Hanson constitute substantial contributions in favour of the research on border regions. In the case of Mexico the effects of trade liberalisation since the mid of the 1980s are analysed in detail. The empirical results of Hanson (1996, 2001) suggest that the expansion of export manufacturing in the Mexican border region significantly contributed to the employment growth in U.S. border manufacturing industries. In recent years some papers provided results for the 1990s which challenge the conclusion of Feenstra/Hanson that international outsourcing is the driving force for increasing wage differentials in developing countries. Airola/Juhn (2005) and Chiquiar (2008) find evidence that between 1990 and 2000 demand for skilled labour increased at a much slower rate in regions highly integrated with the U.S. compared to other Mexican regions. Also with respect to European economic integration studies refer to the Feenstra-Hanson model. Examining nationwide wage differentials Skuratowicz (2005) finds a

growing wage gap between high- and low-skilled workers in Poland. It is quite evident that skill upgrading took also place in the EU accession countries (Bruno et al. 2004). In one of the rare micro-level studies Geishecker/Görg (2008) estimate the effects of international outsourcing on the wages of different skill groups by allowing for individual fixed effects. They find evidence for low-skilled workers being the losers of globalised production, since trade and international outsourcing reduced the real wages in this skill group by up to 1.8%. On the other hand, high-skilled workers benefited from the new trade opportunities by increasing wages up to 3.3%. These results are in line with the findings of Geishecker (2004) stating that with nearly stable relative wages in the 1990s, the decline of the relative demand for low-skilled labour can be explained up to 24% by international outsourcing. Unfortunately, in many cases the analyses are related to whole countries, while there is no reference to regional information, often due to a lack of available data. Though it is beyond all question that skill premiums went up in Western as well as in Eastern European countries, the main cause is still controversial. Since it is above all the effects of free trade and international outsourcing on the development of wage differentials that are disputed, focusing on border regions can contribute to shed light on this topic.

In this paper I highlight the specific situation of the Bavarian-Czech cross-border labour market. While Moritz/Gröger (2007) only use a two percent random sample of all employees not finding significant results I estimate wage effects on the basis of a larger dataset containing all employees subject to social insurance contribution in eastern Bavaria. The remainder of the paper is structured as follows: Data and basic definitions are described in section 2. Section 3 contains descriptive evidence on the qualification structure in the eastern Bavarian border region. In section 4 I analyse wage differentials using an econometric model. Section 5 concludes.

2 Data and Basic Definitions

I use micro data from the weakly anonymous version of the IAB employment subsample (IABS) for the years from 1980 to 2001, which are provided by the Institute for Employment Research (IAB) and contain information about a two percent random sample of all employees covered by the social security system (for a description of the dataset see Hamann 2005). The dataset contains gross earnings which are delivered by the social security agencies and are therefore highly reliable. In order to avoid that observations for the border region are too few and insufficient for robust estimates I include an extract from the employment register (*Beschäftigtenhistorik BeH*), which covers all observations in the eastern Bavarian border

region (i.e. 100% instead of 2%). For all estimations I eliminate apprentices, marginal part-time and part-time workers, homeworkers and all observations where information about education and/or professional status is missing, from the data. I concentrate on full-time employees, aged 16 to 65, who are at least in one year employed on June 30 (the reference date).¹ I distinguish between the following three skill groups of workers (table 1):

Table 1: Classification of German skill groups

Skill group	Qualification
low-skilled	people with no occupational qualification regardless of the educational level reached, i.e. with or without a certificate of upper secondary education (<i>Abitur</i>)
skilled	people with an occupational qualification whether or not they have a certificate of upper secondary education (<i>Abitur</i>)
high-skilled	people with upper secondary education and a degree from a university or polytechnic

Table 2: Regional classification scheme based on BBR classification

Structural region type	District type	Description of district type (BBR)
Regions with large agglomerations (basic type 1)	BBR 1	Core cities
	BBR 2	Highly urbanised districts in regions with large agglomerations
	BBR 3	Urbanised districts in regions with large agglomerations
	BBR 4	Rural districts in regions with large agglomerations
Regions with features of conurbation (basic type 2)	BBR 5	Central cities in regions with intermediate agglomerations
	BBR 6	Urbanised districts in regions with intermediate agglomerations
	BBR 7	Rural districts in regions with intermediate agglomerations
Regions of rural character (basic type 3)	BBR 8	Urbanised districts in rural regions
	BBR 9	Rural districts in rural regions

Source: Federal Office for Building and Regional Planning (*Bundesamt für Bauwesen und Raumordnung BBR*).

¹ The sample contains only employees who are covered by the social security system, i.e. civil servants, self-employed persons and freelancers are excluded.

According to the regulation regarding employment permits for foreign commuters in German border regions (*Anwerbestoppausnahmereverordnung ASAV 1997*) the Bavarian borderland consists of the eastern parts of the regions of *Oberfranken* (Upper Franconia), *Oberpfalz* (Upper Palatinate) and *Niederbayern* (Lower Bavaria) including the university towns of Bayreuth and Passau and the towns with polytechnics (*Fachhochschulen*) Hof, Weiden, Amberg and Deggendorf (15 districts and 7 autonomous municipal authorities, figure 1). In contrast to the border region in ASAV, § 6 para. 1 my analysis covers the city and the district of Regensburg. Taking into account the differences between urban and rural areas I use the classification scheme of the Federal Office for Building and Regional Planning (*Bundesamt für Bauwesen und Raumordnung BBR*), which differentiates between regions with large agglomerations (BBR 1-4), regions with features of conurbation (BBR 5-7) and regions of rural character (BBR 8-9) (table 2). As control group I use the observations only from the remaining western German districts (without Berlin), since the inclusion of data from the eastern German states (which are available from 1992 onwards) would lead to biased results.²

² Due to the unavailability of eastern German data for the time before 1992 it is also impossible to analyse the impact of the fall of the Iron Curtain in districts close to Poland.

Figure 1: Eastern Bavarian border region

3 Some Descriptive Evidence

In order to evaluate the shifts in the relative wage differentials in eastern Bavaria, it is interesting to take a prima facie view at the skill structure. My analysis is motivated by the need to contrast the development in the border region with the average level in western Germany. The absolute deviation (as %) of skill group shares in the border region from the national averages is shown in figure 2. Taking the rather rural structure of eastern Bavaria into consideration I compare the regional values only with district types 5-9 at national level. From 1980 to 2001 the share of low-skilled workers in eastern Bavaria approximates the level of district types which are typical for this region. In contrast to this development I observe a sharp rise in the share of skilled employees in eastern Bavaria: the share, which was distinctly below the aver-

age in 1980, exceeded the national level moderately in 2001. The deficit of high-skilled workers in eastern Bavaria compared with the average level of the district types 5-9 increased only marginally. Border region effects resulting from the fall of the Iron Curtain are obviously not observable at the descriptive level.

4 Econometric Analysis of Wage Differentials

4.1 Separate Regressions for Each Year

The aim of my analysis is to estimate whether the opening of the border between Germany and the Czech Republic had a significant effect on the development of wages of German employees in the eastern Bavarian borderland compared to employees in other western German districts. Firstly, the development of relative wage differentials can be estimated in every year by conventional regression analysis. Focusing on full-time working employees I estimate a Mincerian wage equation (Mincer 1974) by running cross-sectional regressions for each year between 1980 and 2001 separately. I split the dataset into subsamples according to the skill and sex groups.³ The estimation equation takes the following form:

$$\ln WAGE_i = \alpha + \beta_1 EXPER_i + \beta_2 EXPER_i^2 + \sum_{j=1}^{J=3} \gamma_j BBR_{ji} + \sum_{k=1}^{K=27} \delta_k DWZWG_{ki} + \lambda FOREIGN_i + \tau BORREG_i + \phi BORREG_i * FOREIGN_i + \varepsilon_i \quad (1)$$

³ Since I use all observations for the border region from the employment register and only a 2% sample of observations in the non-border region I weight the observations adequately to their representativeness.

For a detailed definition of the variables see table 3. The dependent variable $\ln WAGE$ denotes the logarithm of individual i 's daily wage. Contrary to the regressions in Moritz/Gröger (2007) I do not estimate a Tobit model, but use wages that are in the case of censoring at the upper ceiling in the German social contribution system imputed on the basis of Tobit estimates of the distribution parameters (Gartner 2005), so that I can then apply the standard OLS method. In addition to the variables controlling for the potential experience ($EXPER$, $EXPER^2$) I use dummies for the district types (BBR) and the industries ($DWZWG$).⁴ The branches of economic activity are not aggregated into 16 industries, but are available on the basis of a 3-digit code (WZ 73). I transform this very detailed classification into a scheme of 28 industries. In order to avoid estimations for a reference group of job entrants I include only individuals with at least five years of work experience ($EXPER \geq 5$). Since the district types 1-4 and 6 do not appear in the border region I exclude observations of these districts from the estimation. Moreover, I include a dummy variable for nationality ($FOREIGN$), which equals one if the employee is not German and zero otherwise. The coefficient of $BORREG$, τ , which I am mostly interested in, estimates the wage effect (as %) for German employees of the respective skill and sex group in the border region compared with the national level. According to my hypothesis I expect decreasing values of τ for low-skilled workers and increasing values for skilled and high-skilled workers for the years after 1989. In order to control for foreigners in eastern Bavaria including the Czech commuters who are allowed to work in the Bavarian borderland according to the regulation regarding employment permits for foreign commuters in German border regions (*Anwerbestoppausnahmeverordnung ASAV* 1997), I interact the nationality dummy with the border region dummy ($BORREG*FOREIGN$). The coefficient of this variable measures the wage effect of foreign workers in the border region relative to foreigners in the rest of the country.⁵

⁴ The workers' potential on-the-job experience ($EXPER$) is measured in years as age minus average duration of education minus six. I impose 10 years as the average duration of education for low-skilled workers without upper secondary education, 13 years for low-skilled workers with upper secondary education, 12.5 and 15 years respectively for skilled workers, 16 years for high-skilled workers holding a degree from a polytechnic and 18 years for high-skilled university graduates.

⁵ In a robustness check I separate Czech foreigners from all other foreigners. However, this has no fundamental effect on the coefficient of the most interesting variable $BORREG$.

Table 3: Variables of the wage equation

ln WAGE	logarithm of individual wage
EXPER (≥ 5)	potential job experience
EXPER ²	potential job experience ² /100
BBR*	dummies for BBR district types 5,7 and 8
DWZWG*	dummies for industries 1-27
FOREIGN	dummy for foreign workers
BORREG	dummy for border region
BORREG*FOREIGN	interaction term of BORREG and FOREIGN
cons.	constant

The estimation results of the control variables are sensible. The coefficient of the variable controlling for foreign workers exhibits all along the observation period negative values for all male skill groups and for low-skilled female workers. This means, that foreigners belonging to these groups earn less than the relevant domestic German workers. Positive wage differentials for non-Germans are identified for female skilled workers in the 1990s and in some years for female high-skilled workers. One additional year of potential experience yields in the first instance a significant wage increase, but the benefit decays over time (coefficients of $EXPER +$, $EXPER^2 -$). The significant coefficient values for most of the dummies for district types and industries provide evidence for an agglomeration wage premium as well as for inter-industrial wage differentials.

Concerning the border region dummy I obtain the following results for the coefficient τ : in the case of domestic low-skilled workers an interesting difference between males (figure 3a) and females (figure 3b) is observable. In the 1980s male low-skilled employees in the eastern Bavarian border region earn about 5% less. This wage differential considerably narrows in the beginning of the 1990s to around -3%. Until the end of the decade the wage gap widens again approaching the original level of -5%. In contrast to this surprising development there is no similar trend for low-skilled female workers in the border region. Starting from a far smaller wage gap of approximately -2% the difference increases in the 1980s to about -4%. This level stabilises during the 1990s with only one negative outlier in 1999.

Figure 3: Gender-specific wage effect for German employees in eastern Bavaria (as %, 1980-2001)

Source: Author's own calculations using the IABS and BeH extract.

Notes: In the case of censoring, wages are calculated in the framework of an imputation procedure using the Tobit estimation method; regression with heteroskedasticity-robust standard errors.

Regarding skilled employees a general catching-up process in eastern Bavaria is clearly evident in the estimates, but interestingly, again only for male employees (figure 3c). Earning nearly 5.5% less in 1980 the differential becomes continuously smaller until the mid 1990s at a level of about 3%. Then, similar to the trend for low-skilled male workers, the graph turns to a deeper wage gap of around 4% in 1999 with a slight recovery in the following two years. For female skilled workers the picture is again completely different (figure 3d). Relative wage

losses for employees in the borderland in the 1980s (from -2% to -3%) are succeeded by making them up in the 1990s (from -3% to -2%).

As far as high-skilled workers are concerned, the distinctively smaller number of observations poses a problem (apparent in the figures through the huge confidential bounds). Male high-skilled workers in eastern Bavaria (figure 3e) earn about 1% below average until the mid 1980s. In the following ten years the wage differential is positive and then oscillates around the 0% line. Female high-skilled workers in the border region obviously catch up in the 1980s from below average to above average values. In the 1990s the wage level stabilises around the reference value for western Germany (figure 3f).

4.2 Panel: Fixed Effects

In the previous subsection I split the dataset according to the years from 1980 to 2001 and estimated separately the wage effect in the border region. Since this method has some drawbacks I also apply a fixed effects approach and compare the results. In order to account for the time structure of the data I now use the whole dataset across the years. Since some individuals are observed not only in one period the data have the structure of an unbalanced panel, which entails some advantages. Compared to a series of cross sections the explanatory variables now vary over two dimensions (individuals and time). Moreover, having a larger sample size in only one equation usually leads to more accurate estimators. More intuitively, the data should provide better information since the same individuals are repeatedly observed (Verbeek 2008). Furthermore, the above applied estimation method does not control for unobserved heterogeneity. Individuals exhibit characteristics which are hardly observable. This fact poses a problem if these attributes have an effect on the outcome variable and in addition are correlated with an explanatory variable, i.e. the estimate of this variable will be biased due to endogeneity. In the border region scenario, for instance, employees living there could have characteristics, e.g. regarding career planning and motivation that lead to a lower wage. Omitting these factors in the regression would yield a biased estimate for the variable *BORREG*, which then captures this effect. In order to control for unobserved heterogeneity I apply a fixed effects approach, i.e. I mitigate the omitted variable bias by replacing the constant in the wage equation in the previous subsection with a fixed effect π_i , which captures time-invariant characteristics of the individuals. In this case, the coefficient of the variable *BORREG* reflects the basic wage differential of employees in the eastern Bavarian border region in 1980. It is important to mention that this variable in the fixed effects regression only estimates the effect for movers from the non-border into the borderland against the movers in the opposite direc-

tion. In order to reflect the wage increases over time I include a set of time dummies into the wage equation above, s.th. $YEARI981 = 1$ if $t = 1981$ and so on. While the year 1980 constitutes the base period, the time dummies capture in each year the general trend which does not vary between the individuals. Furthermore, I generate interaction terms between the different years and the border region dummy ($BORREG*YEARI981$ etc.). As these interaction terms control for the difference (over time) in the difference (wage gap in the border region), the coefficients $\omega_1, \dots, \omega_{21}$ represent the difference-in-difference estimators (Wooldridge 2005). The coefficient of an interaction term in a specific year expresses the change in the wage differential of the border region relative to the rest of the country.

A Hausman test rejects in all cases the hypothesis that with respect to a random effects model the differences in the estimated coefficients are not systematic, i.e. the fixed effects model is favoured. Table 4 shows the wage differentials in the reference year 1980 and figure 4 the development in the following years. The results for *BORREG* and the interaction terms are quite plausible. In all cases the coefficient for *BORREG* exhibits a negative sign, in this case with significant values only for all male subgroups. Comparing the course of the graph to the gradient in the previous regressions, there is one striking difference: for all male and female subgroups the wage gap at the end of the observation period (in 2001) is larger than at the beginning (in 1980). Regardless of the trend starting already in the 1980s or be it a reversal in the mid 1990s the decline is more substantial than in my preceding results. This means that controlling for idiosyncratic characteristics of the individuals the relative wages in the eastern Bavarian border region are decreasing, though not everywhere significantly. It is interesting that the catching-up process for male low-skilled and skilled workers is also confirmed using this estimation method. Summarising the results, the trend from the mid 1990s onwards seems generally unfavourable for eastern Bavaria.

Table 4: Basic wage differential for German employees in fixed effects estimations

	BORREG (low-skilled)		BORREG (skilled)		BORREG (high-skilled)	
	Coef. τ	Std. Err.	Coef. τ	Std. Err.	Coef. τ	Std. Err.
male	- 0.0816***	0.0135	- 0.0445***	0.0056	- 0.0949***	0.0308
	N=1,579,214 n=256,058	R ² =0.7573	N=5,610,951 n=647,543	R ² =0.7586	N=362,935 n=60,526	R ² =0.5692
female	- 0.0174	0.0438	- 0.0205	0.0156	- 0.0835	0.0767
	N=1,315,872 n=212,503	R ² =0.6312	N=2,108,504 n=353,526	R ² =0.5791	N=73,356 n=18,321	R ² =0.5197

5 Conclusion

The aim of this paper was to analyse the relative effects of the fall of the Iron Curtain on the eastern Bavarian borderland with respect to wage differentials for German employees. Since this group of workers covered by the social security system constitutes the bulk of the economically active population it is possible to draw conclusions for the labour market as a whole. Therefore, I used the IAB employment subsample (IABS) and the employment register (BeH) and compared the eastern Bavarian wage differential before the opening of the border in the 1980s to the years afterwards until 2001. According to the Feenstra-Hanson model

international trade and international outsourcing strikes the low-skilled workforce in the border region to a higher degree leading to relative wage losses. On the other hand, the higher attractiveness of the region after the abolition of trade impediments should benefit especially high-skilled employees. Regarding wage differentials between eastern Bavaria and the rest of western Germany I applied two estimation methods in order to identify the effects of the open border. In contrast to Moritz/Gröger (2007), who do not find significant results, a larger dataset and advanced methods shed more light on the changes. Using imputed wages and separating between male and female employees I estimated separate wage equations for every year and applied a fixed effects model.

The estimates shed light on differences between male and female workers. The findings are only partly in line with the predictions of the Feenstra-Hanson model. Skilled and high-skilled workers in eastern Bavaria cannot be clearly identified as relative winners of European integration, whereas low-skilled workers only lose out in the second half of the observation period. For male low-skilled and skilled workers in the borderland, representing more than 60% of the eastern Bavarian workforce, a catching-up process can be verified until the mid 1990s. From 1995 onwards the trend reverses and workers in the border region lose out relatively to employees in the rest of western Germany. The findings for all female skill groups and also male high-skilled employees are not so clear-cut. The results of the fixed effects estimation are most striking: for all sex and skill groups the wage gap deepens in the observation period. The question remains whether or not the opening of the border caused this development, and if so, why different skill and sex groups are affected in an unequal manner. After all, there is no change for the worse immediately after the opening of the border, the indications are actually quite positive in the early 1990s. However, from the mid 1990s or so onwards the development in the border region gives cause for concern.

The results prompt the ongoing research on this topic. Since the observation period ends in 2001 the effects of the accession of the Czech Republic into the EU are not investigated in this framework. Moreover, free movement of labour is still largely restricted between Germany and the Czech Republic, i.e. the abolishment of tariffs and the full liberalisation of labour markets at the latest 2011 might cause deeper effects in eastern Bavaria.
